

Isoscaling as a measure of Symmetry Energy in the Lattice Gas Model

G. Lehaut, F. Gulminelli, and O. Lopez

LPC Caen, ENSICAEN, Université de Caen, CNRS/IN2P3, Caen, France

The energetic properties of nuclear clusters inside a low-density, finite-temperature medium are studied with a Lattice Gas Model including isospin dependence and Coulomb forces. Important deviations are observed respect to the Fisher approximation of an ideal gas of non-interacting clusters, but the global energetics can still be approximately expressed in terms of a simple modified energy-density functional. The multi-fragmentation regime appears dominated by combinatorial effects in this model, but the isoscaling of the largest fragment in low energy collisions appears a promising observable for the experimental measurement of the symmetry energy.

In the different stages of the formation of a neutron star, from the explosion of the supernova to the cooling of the proto-neutron star, the baryonic matter is at finite temperature and densities different from the normal equilibrium density of nuclei. To understand these phenomena, a considerable experimental effort is presently devoted to the determination of the nuclear energy-density functional as a function of temperature and density[1, 2, 3, 4]. Many investigations are concentrated on the isovector properties of the system, the so-called symmetry energy, which behavior is still largely unknown. In the mean-field theory, the symmetry-energy term can be approximately reproduced as a simple polynomial function of the density $c_{sym}(\rho) \propto \rho^\gamma$ [5]; finite temperature leads just to a fractional occupation of single-particle levels, and as such does not modify the functional behavior of the interaction energy.

The problem is that at low density the mean-field theory can be severely incorrect[6]. In the heavy-ion collisions which are used to probe the density dependence of the symmetry energy, the system under study is typically inhomogeneous; it is therefore not clear whether, even at thermal equilibrium, the associated energy functional only depends on the global density as obtained in a mean-field based picture.

A simple formula has also been proposed[7] to extract directly the symmetry energy from measured cluster properties obtained in the fragmentation of two systems of charge Z_1, Z_2 , mass A_1, A_2 at the same temperature T :

$$4 \frac{c_{sym}}{T} = \frac{\alpha}{(Z_1^2/A_1^2) - (Z_2^2/A_2^2)} \quad (1)$$

where α is the so-called isoscaling parameter that can be measured from isotopic yields[8].

However eq.(1) has been derived in the framework of macroscopic statistical models [7], where many-body correlations are supposed to be entirely exhausted by clusterisation, and it appears to be strongly affected by conservation laws and combinatorial effects[9, 10]. Moreover, the c_{sym} coefficient appearing in eq.(1) should correspond to the symmetry free-energy[11], which is equivalent to

the symmetry energy only in the $T \rightarrow 0$ limit.

To progress on these issues, it is interesting to consider a microscopic model simple enough to be exactly solvable through Monte-Carlo simulations without any mean-field or independent-cluster approximation. In this paper, we study the temperature and density dependence of the symmetry energy coefficient and its connection to experimental observables in a Lattice Gas Model.

Let us consider a system composed of N neutral and Z charged particles of mass $m = 939 MeV$ occupying a cubic lattice of $V = 8000$ cells with four degrees of freedom : one discrete variable σ_i for isospin ($\sigma_i = \pm 1$ for protons (neutrons), $\sigma_i = 0$ if the site is unoccupied), and three continuous variables $\vec{p}_i$ for the momentum. The Hamiltonian of the system follows:

$$H = \sum_{\langle i,j \rangle} \epsilon_{\sigma_i \sigma_j} \sigma_i \sigma_j + \sum_{\sigma_i = \sigma_j = 1, i \neq j} \frac{I_c}{r_{ij}} + \sum_{i=1}^{L^3} \frac{p_i^2}{2m} \sigma_i^2 \quad (2)$$

where $\langle i, j \rangle$ are nearest neighbor cells, $\epsilon_{\sigma_i \sigma_j}$ is the coupling between nearest neighbor ($\epsilon_{11} = \epsilon_{-1-1} = 0, \epsilon_{1-1} = 5.5 MeV$), $I_c (= 1.44 MeV/fm)$ is the Coulomb coupling between protons, and r_{ij} is the distance between sites i and j . The lattice spacing $r_0 = 1.8 fm$ has been chosen such that a full lattice occupation corresponds to the saturation density of symmetric nuclear matter $r_0^{-3} = \rho_0 = 0.17 fm^{-3}$.

This model has been already shown to be able to give a qualitative description of nuclear fragmentation[12]. Moreover the simplified version with only one type of uncharged particles is well-known to be isomorphous to the Ising model[13], which makes LGM a paradigm of first and second order phase transitions in finite systems.

Calculations are made in the isobar canonical ensemble, which has been shown to be the correct canonical ensemble to describe unbound systems in the vacuum [14]. The partition function reads:

$$\Omega = \sum_{(n)} \exp \left(-\beta \left(H^{(n)} + P R^{3(n)} \right) \right) \quad (3)$$

where the sum runs over all the possible realizations (n)

of the system, and $R^{3(n)}$ is the global extension of the system for each partition (n) defined as:

$$R^{3(n)} = \frac{2(\sum r_i^3 \sigma_i^2)^{(n)}}{(\sum \sigma_i^2)^{(n)}} \quad (4)$$

The partition sum (3) is numerically sampled for each given value of temperature and pressure with standard Metropolis techniques [15].

With only one type of particles, this model is well-known to exhibit a first order transition and a critical point (T_c, P_c) , analogous to the liquid-gas transition. The phase diagram of a finite system can be obtained within the isobar canonical ensemble from the bimodality of the order parameter distribution [16, 17]. At each pressure, the total energy distribution, as well as the distribution of the size of the heaviest cluster produced in each event, present two peaks of the same height at a temperature value, which is recognized as the transition temperature [18]. At this point the fluctuations are maximum, as shown in the left part of Fig.1 for a representative pressure. The ensemble of these transition points give the transition lines which are shown in the right part of Fig.1. We can see that adding a short-range isovector coupling and a long-range repulsive interaction does not qualitatively modify the phenomenology of the liquid-gas transition (continuous line and full symbol). In particular both fluctuations peak at the same temperature (dotted line), showing that the fragmentation transition has a finite latent heat also for charged systems.

But the phase diagram is considerably enriched respect to liquid-gas. Two extra transitions appear at lower temperature which are specific to the nuclear phenomenology: inside the dashed curve, the system is splitted, without any energy jump, into two dominant fragments of similar size, which can be defined as hot fission. This result is close to the findings of ref.[19]. It is interesting to remark that bimodal distributions of the heaviest fragment have been recently observed experimentally[20]. In the following, we will only consider the systems above the residue-fission coexistence line.

The presence of phase transitions implies that Lattice Gas systems are strongly inhomogeneous and clusterized. In this situation, it is not clear whether the energetics of the system can be described by a macroscopic parametrization depending only on the average density, as in the mean-field approximation.

To explore this issue, we try a liquid-drop inspired macroscopic parametrization for the interaction energy of the system:

$$E_{int}^{LD}(\delta, \rho) = (a_v(\rho) + c_{sym}^v(\rho)\delta^2) A + (a_s(\rho) + c_{sym}^s(\rho)\delta^2) A^{2/3} + \alpha_c(\rho)Z^2 \quad (5)$$

Here δ is the isospin asymmetry $\delta = (N - Z)/A$, T is the temperature and $\rho = A/(4/3\pi R^3)$ is an estimation of

FIG. 1: Left side: fluctuation of the total interacting energy (upper part) and of the size of the largest cluster (lower part) as a function of the temperature at $P = 0.3P_c$, for a system with 75 neutrons and 54 protons. Right side: phase diagram. The full line is the liquid (L) -gas (G) coexistence line and the point is the critical point. The symbols with horizontal error-bars give fission (F) -residue (L) transition points. The dashed line is to guide the eye.

the average density of the system, where the mean cubic radius $R^3 = \langle R^{3(n)} \rangle$ from eq.(4) is calculated excluding the monomers ($A = 1$).

This liquid-drop parametrization (LD) uses five macroscopic density dependent parameters to be fitted to the model: a_v is associated to the volume energy, a_s corresponds to the surface energy, c_{sym}^v and c_{sym}^s give the bulk and surface part of the symmetry energy, and α_c corresponds to the Coulomb interaction.

Eleven different systems of mass number $A = 150$ and isospin ratio ranging from $\delta = -1/3$ to $\delta = 1/3$ are simulated at the pressure $P/P_c = 0.3$ and temperatures ranging from $T/T_t = 0.88$ to $T/T_t = 1.1$. This leads to an average volume variation between $\rho/\rho_t = 0.7$ and $\rho/\rho_t = 1.8$. For each simulation, only one event out of 2×10^4 is kept to minimize auto-correlations, and averages are taken over 10^6 events after a thermalization stage of typically 6×10^4 events. The average energy calculated from the Metropolis simulation is confronted to the best fit obtained from eq.(5) on the upper part of Figure 2. With a global $\chi^2/N_{dof} = 5$, we can consider eq.(5) as a reasonable approximation to the exact energetics of the systems. This is a non-trivial result, considering that the quantity ρ entering eq.(5) is never equal to the local density of the system, which is strongly fluctuating.

The density evolution of the macroscopic coefficients extracted from the best fit is plotted on the bottom part of Figure 2. The arrows give the values obtained when

the same fitting procedure is applied to the systems in their ground state[12, 18]. We observe a decrease of all parameters with decreasing density, but the effect on the bulk terms is more important than the effect on the surface terms. Surprisingly, the contribution of the surface term to the symmetry energy appears to be negligible. This is consistent with the findings of ref.[21].

This result is encouraging for the experimental effort of extracting the nuclear matter c_{sym} out of nuclear collisions: in the framework of this model, the low values extracted[1, 2, 3] cannot be due to trivial surface effects[22, 23].

The other interesting point is that the whole temperature dependence of the energetics is entirely embedded in the density dependence of the macroscopic parameters exactly like in the mean-field theory[24] [32]. This is another non-trivial result, because different partitioning of the system could be associated to the same average spatial extension at different temperatures. What Fig. 2 demonstrates is that, at least in the framework of classical physics and in the considered temperature-density range, the density functional approach can be a very good approach even in the presence of high-order correlations.

FIG. 2: Left part: Best fit obtained from the macroscopic parametrization eq.(5) versus the exact average energy at various average volumes and temperatures evaluated by Metropolis. Right part: Evolution of the macroscopic coefficients of eq.(5) with the average density. The arrows give the zero temperature values of the macroscopic coefficients.

This result suggests that it may be possible to extract the density dependence of the symmetry energy even if the system is clustered.

In order to explore this possibility, we now turn to examine the cluster distribution by looking at the isoscaling observable. It is empirically well known that the ratio $R_{21}(N, Z)$ of isotope yields $Y_i(N, Z)$ measured in two reactions labeled (1,2) at the same incident energy but different in isospin has an exponential behavior [8] ac-

cording to :

$$R_{21}(N, Z) = \frac{Y_2(N, Z)}{Y_1(N, Z)} \propto \exp(\alpha N + \beta Z) \quad (6)$$

where α and β are the isoscaling parameters. It is reasonable to imagine that an observable like α which measures the fragment isotopic content should be sensitive to the symmetry energy, and in particular to its density dependence[1]. Going a step forward, one may hope to extract c_{sym} directly from the measured isoscaling through eq.(1).

It has already been observed that isoscaling is well respected in the LGM in the isochore ensemble [25, 26]. The same is true also at constant pressure, as shown for a representative case in the left part of Fig. 3. The α parameter is almost constant with the fragment charge, and decreases with increasing temperature, which corresponds to decreasing density in the isobar ensemble.

The symmetry coefficient extracted from eq.(1) using the value of α averaged from $Z = 2$ to $Z = 7$ is plotted on Fig. 3. We can see that the resulting parameter is almost constant and completely disagrees with the symmetry energy of the model, as already observed in ref.[26]. An alternative approximate formula was derived in the fragmentation regime in refs.[21, 23]:

$$4 \frac{c_{sym}(Z)}{T} = \frac{\alpha(Z)}{(Z^2 / \langle A \rangle_1^2) - (Z^2 / \langle A \rangle_2^2)} \quad (7)$$

where Z is the charge of the considered fragment and $\langle A \rangle_i$ is the mean mass of this fragment as obtained in system $i = 1, 2$. In this expression c_{sym} corresponds to the fragment symmetry energy, which may differ from the one of the source, for instance because of different surface effects[22, 23]. Different values of $c_{sym}(Z)$ (dashed lines in Fig.3) are observed for the different clusters charges applying eq.(7). Indeed α is almost independent of Z , while the isotopic content of the fragments does depend on the fragment size: this is the well known fractionation phenomenon[4, 23, 27]. Since the resulting $c_{sym}(Z)$ are constant for the different densities, eq.(7) appears also inadequate to reproduce the symmetry energy of the model. As discussed in ref.[10], the weak sensitivity of the α parameter to c_{sym} is due to the fact that light cluster yields are dominated by combinatorial probabilities, and do not reflect the thermodynamic properties of the system.

The mass distribution of LGM is dominated by a large percolating cluster which is the order parameter of the fragmentation transition, and contains most information on the thermodynamics[28]. One may then expect that the isotopic distribution of the heaviest cluster produced in each event may be more sensitive to the symmetry energy of the fragmenting system.

The result of applying eq.(7) to the largest cluster is plotted on Figure 3 as a continuous grey line. We observe

a much better agreement, except close to the transition temperature. This may be due to the fact that very huge energy fluctuations are observed at the transition temperature in this canonical model (see Fig.1), while the energy functional eq.(5) depends only on average quantities. We expect that a better agreement will be obtained with a parametrization of the energy functional as a function of excitation energy and density, instead than temperature and density. This will further allow direct comparison with experimental data and will be the object of future investigations [18].

FIG. 3: Left part: isotopic ratio as a function of the neutron number at $T/T_t = 0.95$ for the systems ($N = 75, Z = 75$) and ($N = 91, Z = 59$). Right part: bold black line: symmetry energy of LGM. The other lines give different estimation of c_{sym} from isoscaling. Bold grey line: symmetry energy from the analysis of the biggest fragment. Dashed grey lines: eq.(7), dashed black line: eq.(1).

To conclude, we have presented in this paper a study on the fragment properties at finite temperature and low density in the framework of a simple exactly solvable model .

We have shown that even in thermodynamic configurations close to a phase transition, where the system is highly dishomogeneous and clusterized, the exact average energy can be well described as a simple functional of the overall average density of the system. We have especially focussed our interest on the possible measurement of the density dependence of the symmetry energy, which is a topic of strong current interest in the nuclear physics community. We have shown that, in the framework of this model, the evolution of the symmetry energy term with the temperature and/or density can be traced with the help of the isotopic distribution of the largest cluster produced in each fragmentation event.

Such measurements are presently undertaken by different experimental groups with the MARS recoil separator at Texas A&M[29] and the VAMOS spectrometer cou-

pled with the INDRA $4 - \pi$ array at GANIL [30], and different experiments in this line are planned with future RiB's facilities[31]. Such data should allow an important advance in the understanding of the functional behavior of the nuclear symmetry energy at finite temperature.

 - [32] The same would not be true if we were to calculate the average free energy $f = \langle e \rangle - Ts$ instead than the average energy $\langle e \rangle$, which is needed as an input of macroscopic statistical models. This latter quantity would depend specifically on the temperature because of the entropy term.
